Abstract. The construction industry is considered risky as labor and machinery intense environment interacts with accelerating and overlapping activities. This situation would result in high number of accidents and fatalities. High number of accidents and fatalities lead to additional cost and delay on all stakeholders including public agencies, project owners, development companies, consultants and construction companies. Identifying hazards and quantifying their impacts on construction safety are crucial for planning, budgeting, and management purposes. Safety hazards ranking is a complex process as these hazards are interconnected. There is a gap in the literature to study the interconnections of these hazards along with their frequency of occurrences. To cover this gap, frequency adjusted importance index and ANP (Analytic Network Process) tool was jointly utilized to capture the interconnections and their frequencies based on the results from a survey distributed to construction professionals. The main contribution of this paper to the existing knowledge is to identify and prioritize potential hazards in construction sector by considering their interconnections along with their frequency level of occurrences. This is the first study in the literature to combine frequency adjusted importance index and ANP tool together. After literature review, 42 hazards in 14 categories were identified. These factors were asked to be rated and linked to each other by the survey respondents worldwide. 106 responses were received, analyzed, and ranked considering interconnections. The results from importance index was used as the base for pair-wise comparison for the ANP model. Based on the results from the model, recommendations to industry professionals are provided and presented.

Keywords: Safety hazards; ANP; Multi criteria decision making; Construction industry; Safety factors

1. Introduction

Construction industry is one of the biggest industries worldwide. Deplorable safety
management practices are damaging the reputation of construction sector (Akram et al. 2019). Many workers and equipment interact together to deliver the final project on time. This interaction would mostly result in accidents. Safety performance monitoring should be performed by all stakeholders to avoid injuries and fatalities in the construction sites. The first step in evaluating the safety performance of a construction site is to identify the hazards, and evaluate their priorities and effect, and to take adequate measures to avoid such hazards. Due to the dangers of the construction industry, leading and lagging safety indicators have been developed to measure safety performance and prevent injury (Versteeg et al. 2019). However, evaluating the priorities of the hazards is a complex issue as many of these hazards are interrelated to each other’s. Traditional risk analysis methods are not efficient to analyze nonlinear or complex systems such as construction sites (Jamot and Park, 2019). There is a gap in the literature to study the interconnections of these hazards along with their frequency of occurrences. The main contribution of this paper to the existing knowledge is capturing the frequency of occurrence of these hazards and their natural interconnections through frequency adjusted importance index and a multi criteria decision-making (MCDM) tool of ANP (Analytic Network Process).

Although very few researchers used ANP to study construction safety hazards (Yang et al. 2019, Zhout et al. 2014, Ardeshir and Mohajeri 2018), they failed to address the frequency component. This is the first study in the literature to introduce frequency component to the ANP tool for realistic capturing of hazard rankings.

After literature review, 42 hazards in 14 categories were identified. These were presented in a survey and distributed online to the construction industry experts. 106 responses received, analyzed, and ranked using frequency adjusted importance index and ANP. The results from frequency adjusted importance index was used as the base for pair-wise comparison for the ANP model. The ANP tool reflected the interdependencies between the safety hazards. With the help of ANP, the hazards are linked together in an analytic network to reach a robust model and outcome. The ranked hazards are presented and proper recommendations were made to industry professionals based on the research outputs.

2. Literature Review

There is a growing body of literature on assessing perceptions of safety climate (Marín et al. 2019). Construction sites are known for its complex environments where many unsafe acts and/or unsafe conditions exist (Jamot and Park, 2019). Identifying hazards was done in many studies like (Grill and Nielsen, 2019, Han et al. 2019, Alruqi and Hallowell, 2019, Wang et al. 2016, Zhang et al. 2019, Mohammadi et al. 2018, Newaz et al. 2018. Suo and Zhang, 2017). Gunduz et al. 2017 conducted an extensive literature review to identify 168 observable variables in 16 latent dimensions that affect safety. The study then proposed a multidimensional safety performance model utilizing structural equation modeling.
(SEM) analysis. (Raviv et al. 2016) has utilized the near-miss reports and accident stories resulted from construction to identify hazards, and classified them into five clusters. Analytic hierarchy process (AHP) then was used to assess the severity of each. On the other hand, (Esmaeili et al. 2015) adopted a preconstruction safety management in which he has identified 22 fundamental attributes with highest impact on safety to predict the safety outcome.

Traditional risk analysis methods are not efficient to analyze nonlinear or complex systems such as construction sites (Jamot and Park, 2019). However, asymmetric safety information and inefficient communication between various stakeholders currently limit the effectiveness of safety monitoring in the construction industry (Xu et al. 2019). Traditional risk analysis methods are not efficient to analyze nonlinear or complex systems such as construction sites (Jamot and Park, 2019). Few studies in the literature adopted the use of ANP to rank hazards. Yang et al. 2019 assessed metro construction safety risk by the use of ANP-grey clustering method. Zhout et al. 2014 assessed high-risk hydropower-construction-project work systems hazards by the analytic network process (ANP) and decision-making trial and evaluation laboratory (DEMATEL). (Ardeshir and Mohajer 2018) studied high-rise construction safety culture among job positions with Fuzzy ANP and Fuzzy Decision Trail and Evaluation Laboratory and methods. The past studies usually study one type of construction without considering their frequency of occurrence on the construction site. There is a gap in the literature to study the interconnections of safety hazards along with the consideration of their frequency of occurrences. This study covers this gap in the literature by considering ANP modelling and the frequency of safety hazards together. With the help of ANP, the hazards are linked together in an analytic network to reach a robust model and outcome. In this study, an extensive literature review on topics related to safety hazards in construction projects was conducted. A draft checklist of 42 hazards in 14 categories (site planning and housekeeping; management involvement; handling, storage and use of materials; welding and cutting; concrete and concrete framework; crane and lifting equipment; electrical equipment; hand and power tools & machinery; working at height and protection against falling; personal protective equipment; traffic & transportation control; scaffolding and ladders; fire prevention; excavation, trenching, and shoring) were collected. Table 1 presents the top forty-two hazards utilized in the study with their corresponding references. Based on the identified safety hazards, a questionnaire was prepared and distributed among the construction professionals. The questionnaire helped identify the most significant safety hazards in construction industry.

Next sections will introduce the methodology on frequency adjusted importance index, ANP and the data analysis parts.

3. Methodology
This study gathered a list of 42 safety hazards from literature review. A survey
An approach was adopted as a means of collecting data for the data analysis. The survey aimed to investigate perceptions of the respondents on safety hazards attributes in the construction industry. A ranking analysis was applied between respondents based on their organization type, job designation, industry type, total construction experience, and size of their companies. The respondents were requested to evaluate the attributes based on a (1-9) scale for the importance and frequency levels of the factors. The (1-9) scale is depicted in Figure 1. The survey was sent to construction professionals that play key roles in the construction industry worldwide.

![Scale definition](image)

Fig. 1: Scale definition.

A total number of 106 completed surveys was received from the respondents worldwide. Frequency adjusted importance index and ANP analysis were applied on the collected data. Ranked attributes were interpreted based on the statistical analyses performed. Finally, recommendations to industry professionals were carried based on the outcomes of the data analysis.

### 4. Data Characteristics

An online website tool was employed in developing, distributing the questionnaire and collecting responses. The questionnaire link was sent out by emails or via professional networks worldwide. Data collection resulted in 106 completed questionnaires. Contractors are the largest portion of respondents with 58 responses (54.7%). Consultants, the second largest contributors of the survey, form almost 17% of the total participants. Project engineer and project/construction managers make total of 60% of the responses.

Participants involved in infrastructure, and oil and gas construction projects hold the significant portion of participants with 28% and 23% of responses respectively. Participants were categorized based on total years of work experiences in construction based on four groups, which are 0 to 5 years, 6 to 10, 11 to 15 and more than 16 years. A percentage of 40% of responses, yielded from professionals with experience between 6 and 10 years.

### 5. Data Analysis

One of the objectives of this paper is to get the perceptions of the construction professionals about the major safety hazards in construction projects. Survey participants rated each hazard importance and frequency based on a 1-9 scale.
Participants were asked to evaluate the importance (the impact) of the hazard on safety performance. Frequency was also rated in order to decide on how often the hazard is come across in construction projects.

As an example, considering the factor “Use of weak and deformed forms”, the questions to the respondent related to this hazard are.

- What is the Impact of “Use of weak and deformed forms” on safety performance?
- How often the “Use of weak and deformed forms” would likely to happen on a construction site?

The survey was sent to construction industry professionals. The data analysis is presented in the coming sections.

5.1. **Frequency Adjusted Importance Index (FAII)**

A similar yet inventive ranking approach adopted in this research to rank safety attributes in construction industry is the Frequency Adjusted Importance Index (FAII). This technique considers both the importance and the frequency. In order to calculate the FAII, both the Relative importance index (RII) and the Frequency index (FI) are required. The equations for FAII, RII, and FI are shown equations below.

\[
\text{RII} \% = \frac{\sum I}{A(N)} \times 100 \tag{1}
\]

\[
\text{FI} \% = \frac{\sum F}{A(N)} \times 100 \tag{2}
\]

Where,

- \( I \) = weight given to importance by the respondent (1 to 9).
- \( F \) = weight given to frequency by the respondents (1 to 9).
- \( A \) = the highest weight (in this case is 9).
- \( N \) = total number of respondents (in this case 106)

Based on both the RII (%) and FI% equations, the frequency adjusted importance index will be calculated as follows:

\[
\text{FAII} \% = \frac{\text{RII} \% \times \text{FI} \%}{100} \tag{3}
\]

FAII provides better ranking results because it reflects the effects of importance and frequency all together.

5.2. **Analytic Network Process (ANP)**

The ANP came as a generalized form of the AHP as many decision problems cannot be dealt with as a linear hierarchy structure. This is because of the existence of interdependencies and interaction between the factors. While AHP depends on a hierarchical form of levels of goal, criteria, and sub-criteria, the ANP deals with all
factors as clusters in a network, which are all connected to the main goal (safety performance in this paper). The other advantage of the ANP is the network connecting the clusters and is elements together. The safety performance in construction is a complex decision problem as many factors are interrelated. Hazards of a certain nature and under a certain category can have obvious influence and can develop other risks in a different category. Hence, it cannot be dealt as independent criteria. Similarly, hazards in a certain category can influence hazards under the same category. This is called the inner dependence, while the previously described relation between categories is called the outer dependence. In such problems, ANP would be a very powerful alternative to AHP and other methods. Figure 2 illustrates the proposed ANP model. The model is a network that consists of categories called clusters. Each cluster contains the elements, which are called the hazards.

![ANP safety performance model](image)

Fig. 2: ANP safety performance model.

The safety performance is connected to all clusters. Until this stage, the model is linear and categories are independent. The red and black arrows represent the interdependences, which is the non-linear part of the model. As explained these shows the effect of relevant hazards in influencing others. As an example, the C2H1, “Lack of safety policy” has its influence on C10H2, “Failure in enforcing use of PPE”.

75
The steps to implement ANP model can be seen in Figure 3. Steps one and two are presented in Figure 2. The 3rd step is to develop a pair-wise comparison between the elements in a matrix format and then to put these sub-matrices together to form the unweighted super matrix (Figure 4). The pair-wise comparison is calculated based on FAII ranking of factors. As an example, the FAII rank of C1H2 is 5, while the FAII rank of C1H3 is 29. The difference in ranking is 24. Using linear interpolation to scale the differences in a (1-9) scale by considering the
maximum rank difference of 31 (maximum rank difference is between factors C4H1 and C4H2), the result will be 7/9. The scaling table can be seen in Table 2. And this is inserted in the W11 matrix in Figure 4. The rest of pair-wise comparison was similarly carried out.

</tbody>
</table>

The fourth step is to do pair-wise comparison at the clusters level to develop the cluster matrix. The weight of the cluster is determined by the weights of its components, which are the nodes (in this case “hazards”). The average value of the hazard weight in FAII was already calculated for the main category. As an example, Weight of C1 = (C1H1+C1H2+C1H3)/3, which is (0.32404+0.35800+0.29878)/3 = 0.3269. Similarly, cluster weights were calculated for all main categories.

Multiplication of each block in the unweighted supermatrix by the weight of the corresponding cluster weight will result in the weighted supermatrix. Raising the weighted supermatrix to high power will make it convergent as the limiting matrix. The results are the rank of the hazards, which is given by the priority vector in the limit matrix. These calculations can be carried out with the help of software like Super Decision. The result of FAII and ANP can be seen in Table 3 below.

</table>
From Table 3, it was seen that the top 5 ranked safety hazards based on ANP results are 1) Lack of company’s safety policy 2) Insufficient safety training 3) Failure in enforcing, motivating, and training workers to use PPE 4) No housekeeping (scattered garbage and material, dusts, excessive noise, vibration, etc.) 5) Insufficient safety motivation and incentives.

5.3. Safety Performance Index (SPI)

The previous results will be utilized to measure the safety performance in construction sites. The 42 hazards will be used to measure safety performance in construction sites. These hazards will be used for calculating SPI (safety performance index), which then can be used to measure safety performance in construction sites, compare sites together, and benchmarking. The main idea is to do site inspection focusing on these hazards, and evaluate if the site under inspection is complying with the safety procedures to avoid such hazard. Compliance will be given a weight of 100% and non-compliance will be 0%. Then the safety index will be the site compliance for each hazard, multiplied by the limiting vector of the hazards.

The SPI can be given according to the following formula:

$$SPI = \Sigma L \cdot E \quad (4)$$

Where,

L: the limiting vector resulted from the ANP, which is normalized for all hazards, and the summation will equal to 1.

E: site evaluation of each hazard (0 – 100%) measured by safety expert.

However, the formula is not considering that some of the hazards can be not applicable in some construction sites due to the type of construction. As an example, welding is not considered as hazard in building site, and concrete work can be ignored in a mechanical pipeline project. In such cases, inapplicable hazards are ignored, and then all other hazards will be normalized to the new summation.

The new limiting vector can be called Ln (normalized Limiting vector). The final general formula will be:

$$SPI = \Sigma Ln \cdot E \quad (5)$$

Where,

Ln: the normalized limiting vector.
E: site evaluation of each hazard (0 – 100%) measured by safety expert.

As an example, refer to Table 4 below. It shows the calculation of an SPI for a random construction site. The safety index is found to be 83.7%. The same table is showing the safety index of each main category. C1- “site planning and housekeeping” is 58.3, and C2- “management involvement” is 88.4 etc. that some hazards are not applicable. Each category’s SPI index was calculated by the formula below. This calculation helps the construction team to take action against each category.

$$SPI\ (each\ category) = \frac{\sum Ln. E}{\sum 100*Ln}$$  \hspace{1cm} (6)

### 6. Discussion of Results

42 hazards in 14 categories were identified and offered in a survey after reviewing the literature. The survey was distributed to construction industry professionals. 106 respondents assessed the 42 hazards based on impact (the hazard impact on safety performance in construction projects) and frequency (How often the hazard is likely to happen). The collected data of 106 responses were then analyzed by frequency adjusted importance index.

The resulted ranking of the hazards was then utilized to perform ANP (Analytic Network Process) as a second stage ranking tool in a purpose to reveal the root causes of these hazards. The ANP was selected as it is a powerful multi-criteria decision-making technique for complex problems. The complexity is due to the existence of interdependencies between hazards from or across different categories. It can be concluded from Table 3 that the hazards, which is considered most significant, is the “Lack of company’s safety policy” (ANP rank 1). This is related to the organization safety management at the planning phase of the project. The safety policy is a strong evidence of commitment toward safety and the methods to implement safety procedures on site. It is to be noted that this ranked 19th 335 in FAII. This result shows the strength of the ANP technique in representing the real

</table>
causes, or the latent hazards, which stand behind many hazards. “Insufficient safety training” (ANP rank 2) is another hazard under the management category. This hazard ranked the first in FAII, and to which most of the accident in construction is referred. This hazard is explicit and latent, as many other hazards are connected to it. “Failure in enforcing, motivating, and training workers to use PPE” ranked as third in ANP compared to seventh in FAII. This also considered as a latent or causing hazard of many hazards related to using PPE like the “Failure to use required PPE (fall arrest systems) and safety nets”, which ranked 4th in FAII.

In this study, it has been proved that safety experts shall focus their attention to the root cause of the hazards that is the latent hazards, which actually drive the accidents and injuries. However, focusing on solving the apparent hazards in a reactive way would not improve safety performance and will keep such hazards repeating as long as construction is ongoing. Hence, the most important is to solve the root causes of the problems. From the study, it has been found that management involvement is the most important factor in improving the safety performance by adopting a robust clear safety policy, which shall include safety and craft training, motivation and incentives, and enforcing and accountability toward safety in all levels of the work force. This proactive attitude will help make safety as a culture at the construction sites. Therefore, the recommendation to construction industry leadership is to focus on safety policies and management commitment to safety when selecting their stakeholders of consultants and contractors.

Furthermore, this paper recommends safety experts to identify hazards, prioritize them, and distribute the budget wisely to prevent accidents.

7. Conclusion

High number of accidents and fatalities lead to additional cost and delay on all stakeholders including public agencies, project owners, development companies, consultants and construction companies. The main contribution of this paper to the existing knowledge is to identify and prioritize potential hazards in construction sector through a multi criteria decision-making (MCDM) tool of ANP. This is the first study in the literature to combine frequency adjusted importance index and ANP tool together. Past literature conducted targeting the safety performance evaluation were focusing on identifying the observable hazards and evaluating their apparent effects. A frequency adjusted importance index analysis was carried out in this paper as a first stage by ranking the hazards. The top three hazards according to FAII were 1) insufficient safety training, 2) negative management attitude to safety, and 3) insufficient safety motivation and incentives.

A second stage ranking was done by using the ANP (Analytic Network Process). This technique has proven its benefits in solving complex decision problems due to existence of interdependencies between its parts, which is the case in safety hazards where some hazards are interrelated. The ANP ranking gave a close ranking similar
to FAII where the top three hazards were 1) lack of company’s safety policy, 2) insufficient safety training, and 3) failure in enforcing, motivating, and training workers to use PPE.

The results of both analyses confirm that the role the management plays an important role to improve the safety performance by establishing a safety policy, adopting safety training procedures, enforce safety procedures through incentives, and control measures. The outcome of this paper would help the construction and the safety professionals on assessing and quantifying the most critical safety hazards in construction industry.

Moreover, the construction and safety professionals would utilize the safety performance index calculation to quantitatively measure their site safety level. This study could be extended further by developing a practical tool to measure the safety performance index and conducting case studies on comparison of safety performance index in construction projects.
